#### ABSTRACT

In this study the structural, microstructural, dielectric and conductivity properties of Fedoped CaTiO<sub>3</sub> (CT) ceramic were investigated. These ceramics were successfully synthesis using the conventional solid-state method. The X-ray diffraction and Rietveld refinement results showed that the ceramics at x=0.0, 0.1, 0.2 and 0.3 crystalize in orthorhombic phase with Pmmm space group. While for x=0.4, 0.5 and 0.6, the phase formation changes from orthorhombic to tetragonal phase with P4/mmm group space. The SEM results revealed a semi-spherical shape of grain for lower Fe content ( $\leq 0.4$ ) while at x=0.5 and 0.6 an agglomeration phenomenon is observed. And the observed density of sample at x=0.5 is higher than the other ceramics. The dielectric properties were studied as function of frequency and temperature. The dielectric permittivity  $(\varepsilon'_r)$ decreases as function of frequency at lower frequency region and remain almost independent of frequency at high frequency region in the whole temperature range of *R.T–520* °C. Each converges at high frequency (>10<sup>5</sup> Hz) for all the temperatures. The evolution of  $\varepsilon'_r$  as function of temperature for pure CT ceramic showed a stability at large range of temperature (from R.T to 250°C). For substituted ceramics, we obtained a phase transition which shifted to the lower temperature with the increase of Fe content. And the value of  $\varepsilon'_{r}$ , increases for Fe-doped CT ceramics and reaches a maximal value for x=0.5 which is 50 time bigger than the pure ceramic. The AC conductivity,  $\sigma_{AC}$ , is found to increase rapidly as function of frequency, at low frequency region, and increases linearly at high frequency region which confirm the hopping of electrons related to the conduction mechanism. The  $\sigma_{AC}$  evolution is found to follows the Jonscher's law and the s exponent decreased with the increase temperature which is related to the correlated barrier height (CBH) model. And the  $\sigma_{AC}$  values increase with the increases of Fe content

#### 1. Introduction

Perovskites are a large family of crystalline materials whose name derives from a natural mineral: calcium titanate (CaTiO<sub>3</sub>). The CaTiO<sub>3</sub> find several applications in the field of manufacturing electronic components requiring high stability of electrical properties as a function of temperature. The CaTiO<sub>3</sub> material is active under UV light and present an excellent photo-corrosion resistance with high thermal stability [1,2,3,4] which make it a good candidate as photocatalyst material. At low temperatures, it presents a ferroelectric property and it has been used in electroluminescent devices and sensors. [1,5]. CaTiO<sub>3</sub> is a perovskite-like material of orthorhombic structure with *a* = 5.4398 Å, *b* = 7.6417 Å, and *c* = 5.3830 Å [6]. Its relative permittivity is about 183 at room temperature and 20 to 77 K [7]. In 1943, Naray-

\*Email of corresponding author: najwa.gouitaa@gmail.com

Szabo observed a distortion of the orthorhombic phase during heat treatments. Since then, the phase transitions of the perovskite CaTiO<sub>3</sub> have been fairly studied. Several works have reported a change from the orthorhombic structure (Pbnm) to the cubic structure Pm3m at high temperature. Vogt and Schmahl [8] found a phase transition from the orthorhombic Pbnm phase to the cubic phase Pm3m around 1290 °C; they did not observe any intermediate phase between these two phases. On the contrary, other researchers have reported the existence of one or more intermediate phases between these two phases. Thus, Guyot et. al [9] and Kennedy et. al [10] reported the presence of two intermediate phases between the Pbnm phase and the Pm3m phase. According to Guyot, the orthorhombic type (Cmcm) is stable between 1110 °C and 1250 °C while the tetragonal type is stable above 1250 °C. According to Kennedy, the orthorhombic phase (Cmcm) is stable between 1125 and 1220 ° C and the tetragonal structure (14 / mcm) is found to be stable up to 1500 °C. On the other hand, Redfern [11] reported only one intermediate phase between the two phases Pbnm and Pm3m respectively. This was in fact the tetragonal phase (14 / mcm) which is found to be stable between 1250 and 1350 °C.

Generally, the structural and dielectric properties of CaTiO<sub>3</sub> are improved by appropriate substitutions of the Ca<sup>2+</sup> or Ti<sup>4+</sup> cations in the perovskite network with other types of cations [12, 13]. Recently, extensive studies have been carried out on the influence of different oxide additions on the properties of materials of the type Ca<sub>1-x</sub>M<sub>x</sub>Ti<sub>1-x</sub>M'<sub>x</sub>O<sub>3</sub> (M = Y, Sr, Ba, Pb; M '= Co, Al, Fe, Cr). This class of materials has become very important and has found countless applications in the manufacture of several electronic components [14,15]. The replacement of the Ti<sup>4+</sup> cations by high valence ions creates additional negative charges which are compensated by the positive charges created by the replacement of Ca<sup>2+</sup> by lower valence ions which leads to the electric charge neutrality of the material.

The effects of different substitutions on the electrical properties of CaTiO<sub>3</sub> were reported [16]. The Fe-doped CaTiO<sub>3</sub> ceramic showed a potential application as semiconductorbased photocatalysis with a best photocatalytic activity, with degradation of almost 100 % MB (10 ppm) under UV-visible light for 180 min [17]. The results found showed that the substitution of Fe on the Ti site ensures the highest oxygen-ion and electronic conductivities. Dunyushkina et al. [18] measured the ionic and electronic conductivities of CaTi<sub>1-x</sub>Fe<sub>x</sub>O<sub>3-δ</sub> (x =0-0.5) solid solutions and found that the ionic conductivity is maximal at x = 0.2 of Fe content, in concordance with other works [19, 20].

The conductivity is correlated with some structural changes as function of Fe substitution. However, the electron and x-ray diffraction (XRD) studies [21] show that, in  $Ca_2T_{2-2-x}Fe_{2x}O_{6-x}$  solid solutions with  $0 < x \le 0.4$ , oxygen vacancies are arranged at random, so that the materials retain pseudocubic symmetry; in the composition range  $0.55 \le x < 1$ , the vacancies undergo ordering in the (0k0) plane. McCammon et al. [22] reported that the x = 0.38 material had a well-defined domain structure with domain sizes in the range 5–10 nm. They explained these results by the ordering of oxygen vacancies. In this study we studied the structural change of Fe doped CaTiO<sub>3</sub> ceramics as function of Fe substitution for x=0.0 to 0.6 and correlate it with dielectric and conductivity properties.

So, in this work, we have synthesis the  $Fe^{3+}$  doped  $CaTiO_3$  ceramic using the solid-state method for x=0.0 to 0.6 of Fe content. And we correlate the structural, dielectric and conductivity properties of these ceramics depending on Fe content. We have compared all the obtained results with the other reported works.

## 2. EXPERIMENTAL AND METHOD

The Fe-doped CaTiO<sub>3</sub> ceramics with the general formula: CaTi<sub>1-x</sub>Fe<sub>x</sub>O<sub>3- $\delta$ </sub> for x=0.0 to 0.6 of Fe content, were elaborated by the conventionnel solid-state method. The starting powders are constituted by CaTiO<sub>3</sub>, TiO<sub>2</sub> and Fe<sub>2</sub>O<sub>3</sub> (with high purity higher than 99%, Sigma Aldrich). These precursors were mixed with acetone and stirred for 4 h, then they were dried for 24 h at a temperature of 80 ° C in the oven. After drying, the powder obtained was ground for approximately 45 min, then calcined in the oven at a temperature of 1300 °C. for 4 h then reground for 30 min.

We used the X-ray diffraction (XRD) to determine the structure and crystallographic orientations of materials. This technique studies the X-ray diffraction of a sample after the interaction of these rays with the atoms of the material. The measuring equipment used is Siemens X'Pert diffractometer. The monochromatic X-ray radiation is produced by a copper anticathode K $\alpha$  line. The filter is a nickel pellet (Ni) for filtering the doublet K $\alpha$ 1, K $\alpha$ 2 characterized by an average wavelength  $\lambda k \alpha = 1.5406 \text{ A}^{\circ}$ . The continuous acceleration voltage used is 40 kV and the heating current is 30 mA. The results obtained were fitted using Rietveld refinement with FullProf software.

Then, we have prepared the pellet from the calcined powders. So, the powders obtained are mixed with 2% APV (polyvinyl alcohol) already prepared. The mixture is dried in an oven at 80 °C then grinded. The fine powder obtained is pressed using uniaxial pressure of 6 tons to form a pellet. The pellets obtained are sintered at 1200 °C/6 h with an ascent rate equal to 2 °C./min. The particle size and morphology of the pellets were observed by a scanning electron microscope (SEM) with JSM-IT500HR instrument. The both sides of the pellets are metallized using the silver lacquer a metal layer to study the electrical and dielectric properties measurements. The dielectric properties were studied with Agilent E4980A by varying the temperature from room temperature (R.T) to 550 °C and frequency (from 20Hz to 2MHz).

# 3. RESULTS AND DISCUSSION

# 3.1 X-ray diffraction results

To choose the adequate calcination temperature of the CaTi<sub>1-x</sub>Fe<sub>x</sub>O<sub>3- $\delta$ </sub> (CTF) powders, we study the phase stability as a function of the calcination temperature for sample at x = 0.5 (CT<sub>0.5</sub>F<sub>0.5</sub>), at different temperatures 1100 °C, 1200 °C and 1300 °C for 4 hours. The figure.1 shows the XRD results of these compounds. We can notice, at 1100 °C and 1200 °C, a presence of peaks which were ascribed to perovskite-type structure of tetragonal symmetry (marked with stars) with the highest intensity is at 2 $\Theta$ = 33.5°, and the presence of secondary phases (marked with red points). While at 1300°C, the impurities disappear and the material remains stable and crystallizes in a tetragonal phase. Hence, we have chosen 1300 °C as calcination temperature of all the CaTi<sub>1-x</sub>Fe<sub>x</sub>O<sub>3- $\delta$ </sub> ceramics.

The XRD results  $CaTi_{1-x}Fe_xO_{3-\delta}$  (CTF) ceramics, for x=0.0 to 0.6 of Fe content, are shown in Figure 2 and reveal that all the powders crystallize in a pure phase without the presence of secondary phases expect the sample at x=0.6 of Fe content. For pure CT (x=0.0), we can observe the formation of peaks characteristic of orthorhombic phase while at x=0.6 the tetragonal peaks are found. To study the phase change between these percentages (x = 0.1 to 0.6) or if we have the coexistence of two phases, we used the Rietveld method.

The Rietveld refinement results of CTF ceramics, for x=0.0 to 0.6 of Fe content, are shown in Figure 3. For pure CT (x=0.0), the Figure 3(a) and Table 1, show that the powder crystalizes in

the pure orthorhombic phase with the space group of Pmmm without presence of any secondary phase. These results are in contradiction with those reported by Guyot et. al [9] and Kennedy et. al [10] in which the tetragonal structure (14 / mcm) is stable from temperature above 1250 °C. With the increase in Fe content from 0.0 to 0.3, we notice no change in structure and space group of CTF ceramics. While for  $x \ge 0.4$  the structure of CTF changes from orthorhombic to tetragonal phase with P4/mmm space group and we observe an appearance of secondary phases for x=0.6 (indicated by stars) which is probably due to the Ti-site saturation. So, we haven't detected a phase mixture in these ceramics like for the Fe-doped BaTiO<sub>3</sub> ceramics [23] in which we have found a coexistence of two phases for x=0.10 to 0.30 of Fe contents. These results are not the same to those reported by L. A. Dunyushkina et. al [18] for the same ceramics, in which they found that the Fe-doped CaTiO<sub>3</sub> have a cubic symmetry.

The effect of Fe<sup>3+</sup> substitution on the lattice parameters and the unit cell volume values is shown in Table 1. The change in these parameters depending on doping rate is related to the ionic radii of Fe<sup>3+</sup> (0.76 Å), which may substitute Ca<sup>2+</sup> (0.06 Å), Ti<sup>2+</sup> (0.80 Å) or Ti<sup>4+</sup> (0.64 Å), or it is due to the presence of vacancies. However, at low Fe rate (x =0.1), Fe<sup>3+</sup> may substitute Ti<sup>4+</sup> or there is a creation of vacancies which causes an increase in the lattice constants and, so an expansion of the unit cell. While at high Fe concentration (x=0.2 and 0.3), Fe<sup>3+</sup>may replace Ca<sup>2+</sup> and / or Ti<sup>4+</sup>, which cause a decrease of the lattice constants that caused contraction in the unit cell.

## **3.2 SEM results**

The Figure 4 shows the SEM micrographs of pure CaTiO<sub>3</sub> and Fe-doped CaTiO<sub>3</sub> samples sintered at 1200 °C for 6h. As it is shown, the size and morphology of the samples change depending on Fe content. However, the sample particles have a semi-spheric shapes for x=0.0 and 0.1 while those at x=0.2 to 0.4 show a quadratic shape. According to Gheffar KhKara et. al [24], the spherical shape is attributed to the CT material, this is why it is observed in samples with low Fe rate. For x=0.5, we can't observe a grain shape due to the high grain size. This sample exhibit a high density which decreases for x=0.6 sample because the latter contain a significant number of pores. In addition, the substituted ceramic's particles, at 0.6 of Fe content, show a significant agglomeration phenomenon. Which is related to highly reactive nature of Fe ions [25,26]. This agglomeration phenomenon was also observed by He Yang et. al for Fe-doped CaTiO<sub>3</sub> ceramics as function of calcination temperature [26] and Fe substitution content [28]. We can also notice a clear decrease in grain size for x = 0.1, 0.2 and 0.3 of Fe content which is equal to 3.32, 2.675, 1.89 µm respectively, and above 0.3 of Fe rate, the grain size increases significantly. The same grain size evolution was reported in our previous work for Fe-doped BaTiO<sub>3</sub> ceramics (for x=0.0 to 0.6) [29]. The decrease in grain size is caused by the creation of oxygen vacancies which generate a lattice distortion, found in XRD results. However, Ohno et. al. [30]. reported a crystal growth inhibition for Fe-doped CaTiO<sub>3</sub> related to the oxygen vacancies that create a pining site and cause a decrease of ion mobility.

**Figure 4.** SEM Micrographs of CTF pellets for x= (a) 0.0; (b) 0,1; (c) 0.2; (d) 0.3; (e) 0.4; (f) 0.5 and (g) 0.6.

# 3.3 Dielectric properties

The frequency dependence dielectric permittivity for CTF ceramics (at x=0.0 to 0.6) is shown in Figure 5. All the ceramics follow the same behavior named classical ferroelectrics behavior. However, the dielectric permittivity is high at low frequency region and decreases rapidly with the increase of frequency after that it remain constant at high frequency region. This evolution of dielectric permittivity as function of frequency is related to the interfacial polarization known by Maxwell–Wagner. The high value of the dielectric permittivity, at low frequency, is due to the presence of a polarization of the space charges at the grain boundaries, generating a potential barrier which leads to an increase in the values of the real part of the permittivity [31]. To explain the decrease in the real part of the permittivity at high frequencies, it is assumed that the dielectric structure is composed of grains of low resistance separated by fine and weakly conductive grain boundaries. With the applied of electric field, the interfacial polarization is created due to the localized accumulation of charges [32].

The effects of Fe<sup>3+</sup> doping ions on the temperature dependence of the dielectric properties of the CT ceramics are shown in Figure 5. Notably, the Fe<sup>3+</sup> doping ions can enhance the temperature stability of  $\epsilon'_r$ . However, the dielectric permittivity of CT ceramic (Figure 6(a)) does not change with temperature variation at a large range of temperature from R.T to 250 °C, after that it increase rapidly. The same behavior is observed for x=0.1 and 0.2 of Fe contents (figure.6. b and c). While for x ≥0.3, the dielectric permittivity is no longer stable as function of temperature, it increases and reaches a maximum showing a phase transition  $T_m$ . This phase transition presents a diffuse phenomenon which become more important with the increase of frequency and it shifts to the lower temperature with the increase in Fe content (Table.2). The same behavior is reported in our previous work for Fe doped BaTiO<sub>3</sub> ceramic [23].

From Table 2, We can also notice that the dielectric permittivity for substituted ceramics (from x=0.1 to 0.5) is higher than the pure CT and it is maximal for x=0.5 then it decreases for x=0.6 of Fe content. However, the lower value of  $\varepsilon'_r$  at x=0.6 of Fe content is due to the appearance of

pores in this sample. While  $\varepsilon'_r$ , for the sample at x=0.5, has a colossal value which is about 50 time bigger than the pure CT ceramic which is probably due to the high density of this pellet found in SEM results. So, the dielectric properties of CT ceramic are improved by Fe substitution. This dielectric permittivity evolution differs from the results of BT substituted with Fe [22]. In which the Fe substitution decreases the  $\varepsilon'_r$  value of BaTiO<sub>3</sub> ceramic.

Regarding the  $\varepsilon'_r$  value of Fe-doped BaTiO<sub>3</sub> sample prepared by solid state method [22] and this of Fe doped-CaTiO<sub>3</sub> in this study, these materials can be used for passive components into various type of dielectrics regarding to their functionality. Based on these values, the Fe-BaTiO<sub>3</sub> have a lower  $\varepsilon'_r$  value, at high temperature, which can be useful at Class 1 of dielectric capacitors named COG, while Fe-CaTiO<sub>3</sub> with higher  $\varepsilon'_r$  value can be applicated for Class 2 of dielectric capacitors named X5R. These two dielectrics codes of Class 1 and 2 were been classified by the Electronic Industries Alliance (EIA) [33].

#### 3.4 Ac conductivity study

In Press, Accepted Manuscript – Note to user

Figure 7(a) shows the evolution of Ac conductivity as a function of frequency in the frequency range of 20 Hz–2 MHz at different temperatures in the range of R.T to 520 °C for CTF ceramic at x=0.1. It can be seen that  $\sigma_{AC}$  increases rapidly, at low frequency region, as the frequency is increased because the admittance of the capacitor is numerically larger than the admittance of the resistor as the frequency increases. Above 10<sup>5</sup> Hz of frequency (high frequency region), the  $\sigma_{AC}$  increases linearly with increasing frequency. This linear increase of  $\sigma_{AC}$  with increasing frequency is probably related to the hopping of electrons, atoms, and motion between sites [34].

The dispersion in conductivity in these ceramics can be described by Jonscher's law [35] according to the relation (1):

$$\sigma_{\omega} = \sigma_{dc} + A \,\omega^{s}. \tag{1}$$

Where  $\sigma_{\omega}$  is the AC conductivity,  $\omega = 2\pi f$  is the angular pulsation, and s is the power law exponent, 0 < s < 1. And A is a constant which dependent poorly on temperature.

The values of exponent s at different temperatures of CTF (for x=0.1) ceramic are tabulated in Table 3. These values of s are determined from the slope of the linear  $\sigma_{AC}$  versus frequency curve. The s values are between 0.40 and 0.99 and s decreases with increasing temperature. This behavior of s with temperature variation shows a conduction mechanism in these ceramics which is related to the barrier jump model correlated (CBH), according to which the transport of charges occurs between localized states related to a jump of the potential barriers. We have found the same variation of s for Fe-substituted BaTiO<sub>3</sub> ceramics [23].

The  $\sigma_{AC}$  exhibits similar curve shapes with increasing of frequency and at different temperature values for other doped samples. The Figure 6(b) shows  $\sigma_{AC}$  as function of temperature for pure and substituted CTF ceramics (for x=0.0 to 0.6) at R.T. As expected, the  $\sigma_{AC}$  values increases with the increase of Fe content for all the substituted ceramics which makes its capacitive applications difficult. The same effect of Fe substitution on conductivity values are reported in our previous work [23], and were also reported by S.J.T. Vasconcelos et. al [36] for CaTiO<sub>3</sub>-LaFeO<sub>3</sub> ceramics. But this result contradicts with those found by L.A Dunyushkina which reported that the conductivity is maximal at 0.2 of Fe content then it decreases.

#### Conclusion

The CaTi<sub>1-x</sub>Fe<sub>x</sub>O<sub>3-6</sub> (CTF) powders were successfully using the conventionnel solid-state method. The X-ray diffraction results confirm the orthorhombic phase formation for x≤0.3 while above this rate the structure changes from orthorhombic to tetragonal phase. The microstructure of the sintered samples showed a decrease in grain size for x≤0.3 then it increases for x=0.4 and 0.5. In addition, the density of sample at x=0.5 is higher. The dielectric properties of CTF ceramics revealed a phase transition for substituted ceramics which shifted to the lower temperature with the increase in Fe doping. And  $\varepsilon'_{r}$  were improved for substituted ceramics especially for x=0.5 which is 50 time bigger than the pure CT ceramic. This highest permittivity in this study is related to the highest relative density found for this sample. For this, the CTF (at x=0.50) can be used in ceramic capacitors and high energy density storage applications. On the other hand, the AC conductivity,  $\sigma_{AC}$ , is found to follow the Jonscher's law. The frequency exponent s decreases with increasing temperature, so the results of the  $\sigma_{AC}$  are related to the correlated barrier height (CBH) model. And the AC conductivity value increases with the increase of Fe content.
